

Correlations among new CP violating effects in $\Delta F = 2$ observables

Andrzej J. Buras and Diego Guadagnoli

Physik-Department, Technische Universität München, D-85748 Garching, Germany

(Dated: June 6, 2008)

We point out that the observed CP violation in $B_d - \bar{B}_d$ mixing, taking into account the measured ratio $\Delta M_d/\Delta M_s$, the recently decreased lattice value of the non-perturbative parameter $\hat{B}_K$ and an additional effective suppression factor $\kappa_\epsilon \simeq 0.92$ in ϵ_K neglected so far in most analyses, may be insufficient to describe the measured value of ϵ_K within the Standard Model (SM), thus hinting at new CP violating contributions to the $K - \bar{K}$ and/or $B_d - \bar{B}_d$ systems. Furthermore, assuming that $\Delta M_d/\Delta M_s$ is SM-like, the signs and the magnitudes of new physics effects in ϵ_K and in the CP asymmetries $S_{\psi K_s}$ and $S_{\psi\phi}$ may turn out to be correlated. For example, in a scenario with new CP-phases in B_d and B_s mixings being approximately equal and negative, a common new phase $\approx -5^\circ$ could remove the tension between ϵ_K and $S_{\psi K_s}$ present in the SM and simultaneously accommodate, at least partly, the recent claim of $S_{\psi\phi}$ being much larger than the SM expectation. We emphasize the importance of precise determinations of V_{cb} , $\hat{B}_K$, F_K and ξ_s , to which the parameter ϵ_K and its correlation with the CP violation in the $B_d - \bar{B}_d$ system are very sensitive.

1. Introduction

The major task achieved in quark flavour physics up to the present is a sound test of the Standard Model (SM) mechanism of flavour and CP violation. This mechanism has proven to be able to accommodate dozens of measured processes, to a degree of accuracy sometimes unexpected. These processes have consequently allowed a redundant determination of the CKM matrix parameters, in particular $\bar{\rho}, \bar{\eta}$. Indeed, the $(\bar{\rho}, \bar{\eta})$ -plots by the UTfit and CKMfitter collaborations have become somewhat an icon of the SM performance in flavour physics. To the present level of accuracy, the ‘big picture’ in flavour and CP violation looks therefore quite solid.

Nonetheless, hints of discrepancies with respect to the SM expectations do exist in some flavour observables. The most recent is the claim of a B_s mixing phase much larger than the SM prediction. This conclusion – first signalled in 2006 by Lenz and Nierste [1] – has been recently reported as an evidence by the UTfit collaboration [2] on the basis of a combined fit to the time-dependent tagged angular analyses of $B_s \rightarrow \psi\phi$ decays by the CDF [3] and DØ [4] collaborations. The result of [2] urges higher-statistics data from Tevatron, but, if confirmed, would be the first evidence of physics beyond the SM from collider data.

Another emblematic example, also emphasized in [2, 5], is that of the penguin-dominated non-leptonic $b \rightarrow s$ decays. The mixing-induced CP asymmetries measured in these decays allow to access $\sin 2\beta$, where β is one of the angles of the Unitarity Triangle (UT), defined below in eq. (3). The $\sin 2\beta$ determinations obtained from these decay modes are systematically lower than the value measured in the tree-level decay $B_d \rightarrow \psi K_s$. The latter direct determination has in turn been found to be lower than the one extracted indirectly from tree-level measurements, in particular $|V_{ub}/V_{cb}|$

[6–8]. Conclusions in this respect depend mostly on the $|V_{ub}|$ estimate, which is a not yet settled issue. Independently of this, the problem has been recently revived in [5] as a consequence of a new lattice estimate of the $\hat{B}_K$ parameter [9], which reads: $\hat{B}_K = 0.720(13)(37)$.¹ The parameter $\hat{B}_K$ enters the CP-violating observable ϵ_K and, in the context of the SM, the decrease of $\hat{B}_K$ found in [9, 10] with respect to previous determinations favors $\sin 2\beta$ again substantially higher than the one extracted from $B_d \rightarrow \psi K_s$.

Here we would like to gather these pieces of information and try to address the question whether existing data on the B_d and K systems do already signal the presence of inconsistencies in the SM picture of CP violation from a somewhat different point of view than the analysis in [5]. More concretely, the most updated theoretical input in K physics – in particular the quite low central value from the aforementioned new lattice determination of $\hat{B}_K$ and an additional effective suppression factor $\kappa_\epsilon \simeq 0.92$ in the SM ϵ_K formula neglected in most analyses to date – tend both to lower the SM prediction for $|\epsilon_K|$ beneath its measured value if the amount of CP violation in the B_d system, quantified by $\sin 2\beta$ from $B_d \rightarrow \psi K_s$, is used as input.

In order to cure this potential inconsistency, one should then introduce either a new CP phase in the B_d or respectively in the K system, or alternatively two smaller phases in both systems. The case of a single additional B_d mixing phase is especially interesting. In this instance, the SM formula

¹ Similar results have been obtained in [10], while $\hat{B}_K = 0.83(18)$ has been reported in [11]. It may also be interesting to note that some non-lattice estimates of $\hat{B}_K$, e.g. those in the large N_c approach, feature $\hat{B}_K \lesssim 0.70$. See in particular refs. [12–14].

for the mixing-induced CP asymmetry $S_{\psi K_s}$ generalizes to

$$S_{\psi K_s} = \sin(2\beta + 2\phi_d) = 0.681 \pm 0.025, \quad (1)$$

where ϕ_d is the new phase. The information mentioned above points toward a small *negative* value of ϕ_d . On the other hand, the mixing-induced CP asymmetry $S_{\psi\phi}$ is given by [7]

$$S_{\psi\phi} = \sin(2|\beta_s| - 2\phi_s), \quad (2)$$

where the SM phases β, β_s are defined from the CKM matrix entries V_{td}, V_{ts} through

$$V_{td} = |V_{td}|e^{-i\beta}, \quad V_{ts} = -|V_{ts}|e^{-i\beta_s}, \quad (3)$$

with $\beta_s \approx -1^\circ$. From eq. (2) one finds that a negative ϕ_s is also required to explain the claim of [2]. It is then tempting to investigate whether, at least to first approximation, the same new phase $\phi_d \approx \phi_s \approx \phi_B$ could fit in both B_d and B_s systems, being a small correction in the former case – where the SM phase is large – and the bulk of the effect in the latter.²

The rest of this paper is an attempt to explore the above possibilities in more detail. For the sake of clarity, we introduce here some notation details. The amplitudes for B_q ($q = d, s$) meson mixings are parameterized as follows

$$\langle B_q | \mathcal{H}_{\Delta F=2}^{\text{full}} | \bar{B}_q \rangle \equiv A_q^{\text{full}} e^{2i\beta_q^{\text{full}}}, \quad (4)$$

where, to make contact with the conventions on the SM phases β, β_s , one has

$$\begin{aligned} \beta_d^{\text{full}} &= \beta + \phi_d, \\ \beta_s^{\text{full}} &= \beta_s + \phi_s. \end{aligned} \quad (5)$$

The magnitudes A_q^{full} can be written as

$$\begin{aligned} A_q^{\text{full}} &= A_q^{\text{SM}} C_q, \\ \text{with } A_q^{\text{SM}} &\equiv |\langle B_q | \mathcal{H}_{\Delta F=2}^{\text{SM}} | \bar{B}_q \rangle| = \Delta M_q^{\text{SM}}/2. \end{aligned} \quad (6)$$

Concerning C_q , with present theoretical errors on the B_q system mass differences ΔM_q , it is impossible to draw conclusions on the presence of NP. Therefore, one typically considers the ratio $\Delta M_d/\Delta M_s$, where the theoretical error is smaller, and is dominated by the uncertainty in the lattice parameter ξ_s , defined as

$$\xi_s \equiv \frac{F_{B_s} \sqrt{\hat{B}_s}}{F_{B_d} \sqrt{\hat{B}_d}}. \quad (7)$$

The resulting SM prediction for $\Delta M_d/\Delta M_s$ is in good agreement with the experimentally measured ratio³. Hence it is plausible, at least to first approximation, to assume $\Delta M_d/\Delta M_s$ as unaffected by NP, i.e., recalling eq. (6), that

$$C_d = C_s = C_B. \quad (8)$$

We will comment on this assumption later on in the analysis.

2. ϵ_K and $\sin 2\beta$

We start our discussion by looking more closely at the ϵ_K parameter. For the latter, we use the following theoretical formula [16]

$$\begin{aligned} \epsilon_K &= e^{i\phi_\epsilon} \sin \phi_\epsilon \left(\frac{\text{Im}(M_{12}^K)}{\Delta M_K} + \xi \right), \\ \xi &= \frac{\text{Im} A_0}{\text{Re} A_0}, \end{aligned} \quad (9)$$

with A_0 the 0-isospin amplitude in $K \rightarrow \pi\pi$ decays, $M_{12}^K = \langle K | \mathcal{H}_{\Delta F=2}^{\text{full}} | \bar{K} \rangle$ and ΔM_K the $K - \bar{K}$ system mass difference. The phase ϕ_ϵ is measured to be [17]

$$\phi_\epsilon = (43.51 \pm 0.05)^\circ. \quad (10)$$

Formula (9) can for instance be derived from any general discussion of the $K - \bar{K}$ system formalism, like [18, 19], and can be shown to be equivalent to eq. (1.171) of [20], where all the residual uncertainties are explicitly indicated and found to be well below 1%. In contrast with the ϵ_K formula used in basically all phenomenological applications, eq. (9) takes into account $\phi_\epsilon \neq \pi/4$ and $\xi \neq 0$. Specifically, the second term in the parenthesis of eq. (9) constitutes an O(5%) correction to ϵ_K and in view of other uncertainties was neglected until now in the standard analyses of the UT, with the notable exception of [21, 22]. Most interestingly for the discussion to follow, both $\xi \neq 0$ and $\phi_\epsilon < \pi/4$ imply suppression effects in ϵ_K relative to the approximate formula. In order to make the impact of these two corrections transparent, we will parameterize them through an overall factor κ_ϵ in ϵ_K :

$$\kappa_\epsilon = \sqrt{2} \sin \phi_\epsilon \bar{\kappa}_\epsilon, \quad (11)$$

with $\bar{\kappa}_\epsilon$ parameterizing the effect of $\xi \neq 0$. The calculation by Nierste in [20] (page 58), the analyses in [21, 22] and our very rough estimate at

² This simple correlation is unrelated to more involved correlations that invoked $\Delta F = 1$ transitions, as in [15] and references therein.

³ Variations of the SM formula due to different CKM input are much smaller than the relative theoretical error, which is roughly $2 \times \sigma_{\xi_s}$.

the end of the paper show that $\bar{\kappa}_\epsilon \lesssim 0.96$, with 0.94 ± 0.02 being a plausible figure. Consequently we find

$$\kappa_\epsilon = 0.92 \pm 0.02. \quad (12)$$

In view of the improvements in the input parameters entering ϵ_K , the correction (12) may start having a non-negligible impact in UT analyses. Therefore, a better evaluation of this factor would certainly be welcome.

One can now identify the main parametric dependencies of ϵ_K within the SM through the formula

$$|\epsilon_K^{\text{SM}}| = \kappa_\epsilon C_\epsilon \hat{B}_K |V_{cb}|^2 \lambda^2 \bar{\eta} \times \\ (|V_{cb}|^2 (1 - \bar{\rho}) \eta_{tt} S_0(x_t) + \eta_{ct} S_0(x_c, x_t) - \eta_{cc} x_c), \quad (13)$$

with $C_\epsilon = \frac{G_F^2 F_K^2 m_{K^0} M_W^2}{6\sqrt{2}\pi^2 \Delta M_K}$,

and where notation largely follows ref. [18], in particular $x_i = m_i^2(m_i)/M_W^2$, $i = c, t$. As far as CKM parameters are concerned, eq. (13) reproduces the ‘exact’ SM result, where no expansion in λ is performed, to 0.5% accuracy. Now, $1 - \bar{\rho} = R_t \cos \beta$ and $\bar{\eta} = R_t \sin \beta$, where the UT side R_t is given by

$$R_t \approx \frac{1}{\lambda} \frac{|V_{td}|}{|V_{ts}|} \\ = \frac{\xi_s}{\lambda} \sqrt{\frac{M_{B_s}}{M_{B_d}}} \sqrt{\frac{\Delta M_d}{\Delta M_s}} \sqrt{\frac{C_s}{C_d}}. \quad (14)$$

with $C_d = C_s$ assumed here (see eq. (8)) and ξ_s introduced in eq. (7). Therefore, for the leading contribution to ϵ_K , due to top exchange, one can write

$$|\epsilon_K| \propto \kappa_\epsilon F_K^2 \hat{B}_K |V_{cb}|^4 \xi_s^2 \frac{C_s}{C_d} \sin 2\beta, \quad (15)$$

showing that the prediction for ϵ_K is very sensitive to the value of $|V_{cb}|$ but also to ξ_s and F_K . All the input needed in eqs. (13)-(15) and in the rest of our paper is reported in table I.

3. Three new-physics scenarios

Next we note that the most updated values for all the parameters on the r.h.s. of eq. (15), with exception of $\sin 2\beta$, are lower with respect to previous determinations. Notably, the central value of the most recent estimate of $\hat{B}_K$ [9] is lower by roughly 9%, with a similar effect due to the κ_ϵ factor (see eq. (12)). One can then investigate whether the value of $\sin 2\beta$ required to accommodate $|\epsilon_K|$ within the SM may be too high with respect to the $\sin 2\beta$ determination from B_d physics,

$G_F = 1.16637 \cdot 10^{-5} \text{ GeV}^{-2}$	$\lambda = 0.2255(7)$	[23]
$M_W = 80.403(29) \text{ GeV}$	$ V_{cb} = 41.2(1.1) \cdot 10^{-3}$	[24]
$M_Z = 91.1876(21) \text{ GeV}$	$\eta_{cc} = 1.43(23)$	[25]
$\alpha_s(M_Z) = 0.1176(20)$	$\eta_{ct} = 0.47(4)$	[25]
$m_c(m_c) = 1.25(9) \text{ GeV}$	$\eta_{tt} = 0.5765(65)$	[26]
$M_t = 172.6(1.4) \text{ GeV}^a$	$F_K = 0.1561(8) \text{ GeV}$	[23]
$M_{B_d} = 5.2795(5) \text{ GeV}$	$M_{K^0} = 0.49765 \text{ GeV}$	
$M_{B_s} = 5.3661(6) \text{ GeV}$	$\Delta M_K = 0.5292(9) \cdot 10^{-2} / \text{ps}$	
$\Delta M_d = 0.507(5) / \text{ps}$	$ \epsilon_K = 2.232(7) \cdot 10^{-3}$	
$\Delta M_s = 17.77(12) / \text{ps}$	$\kappa_\epsilon = 0.92(2)$	
$\xi_s = 1.21(6)$	$\phi_\epsilon = 43.51(5)^\circ$	

^aThe $\overline{\text{MS}}$ mass value $m_t(m_t) = 162.7(1.3)$ is derived using [27].

TABLE I: Input parameters. Quantities lacking a reference are taken from [17].

as already investigated in [5] for $\kappa_\epsilon = 1$. Here we would like to emphasize that, more generally, this could entail the presence of a new phase either dominantly in the B_d system or respectively in the K system, or, alternatively, of two smaller phases in both systems, defining in turn three NP scenarios. Addressing the significance of either scenario crucially depends on the errors associated with the theoretical input entering the ϵ_K^{SM} formula. We will come back to this point quantitatively in the discussion to follow, where all the present uncertainties are taken into account.

However, since these uncertainties in the input do not yet allow clear-cut conclusions, we would like to first illustrate the three just mentioned NP scenarios by setting all input parameters except $\hat{B}_K$ at their central values. This would correspond to the hypothetical situation in which all the input, including the CKM parameters, were controlled with higher accuracy than $\hat{B}_K$, for which we assume a 3% uncertainty. In fig. 1 (left panel) we then show $|\epsilon_K^{\text{SM}}|$ as a function of $\sin 2\beta$ for $\hat{B}_K \in \{0.65, 0.70, 0.75, 0.80\} \pm 3\%$. The vertical ranges centered at $\sin 2\beta \in \{0.681, 0.75, 0.88\}$, with a relative error chosen at 3.7% as in the $\sin 2\beta_{\psi K_s}$ case, define the scenarios in question. The horizontal range, representing the experimental result for ϵ_K , shows that $\sin 2\beta \approx \sin 2\beta_{\psi K_s}$ would require NP in ϵ_K in order to fit the data, unless $\hat{B}_K \gtrsim 0.85$. Conversely, in the last scenario, as considered in [5], no NP is required to fit the data on ϵ_K , even for $\hat{B}_K \approx 0.65$. In this case, however, the discrepancy with respect to the $\sin 2\beta_{\psi K_s}$ determination reveals the need for a NP phase in the B_d system around -9° . In table II we report indicative values for various quantities of interest obtained from the scenarios shown in fig. 1 (left panel). In particular, values for $|\epsilon_K^{\text{SM}}|$ are shown for $\hat{B}_K = \{0.7, 0.8\}$. In giving the result for $S_{\psi\phi}$ we set $\phi_d = \phi_s$ (see discussion below). We observe that values of $\hat{B}_K$ in the ballpark of 0.7 would imply a NP correction to $|\epsilon_K^{\text{SM}}|$ exceeding

FIG. 1: Left panel: $|\epsilon_K^{\text{SM}}|$ vs. $\sin 2\beta$ with only $\hat{B}_K$ errors included. $\hat{B}_K \in \{0.65, 0.70, 0.75, 0.80\} \pm 3\%$ are shown as blue areas (darker to lighter). Vertical green areas display $\sin 2\beta \in \{0.681, 0.75, 0.88\} \pm 3.7\%$ (see text). Right panel: γ vs. $|V_{ub}|$ for $\sin 2\beta \in \{0.681, 0.75, 0.88\} \pm 3.7\%$ (green areas). Displayed in blue is the area corresponding to $R_t = R_t^{\text{SM}}$, while orange lines represent the contours of ϵ_K^{exp} .

	$\sin 2\beta$		
	0.681	0.75	0.88
$10^3 \cdot \epsilon_K^{\text{SM}} \begin{cases} \hat{B}_K = 0.7 \\ \hat{B}_K = 0.8 \end{cases}$	1.71	1.90	2.27
$\phi_d [^\circ]$	0	-2.8	-9.4
$S_{\psi\phi}$	0.04	0.14	0.36
$10^3 \cdot V_{ub} $	3.50	3.92	4.90
$\gamma [^\circ]$	63.5	64.0	63.9

TABLE II: Indicative values for various quantities of interest in the scenarios represented in the left panel of fig. 1 (see also text).

+20%, which should be visible if the input parameters could be controlled with, say, 2% accuracy.

The above discussion, and the scenarios in table II, assume that the UT side R_t be equal to its SM value (see eq. (8)) and imply γ not larger than around 65° . Figure 1 (right panel) shows the correlation existing for fixed $\sin 2\beta$ between γ and $|V_{ub}|$ (or, equivalently, the side R_b [34]). From the figure one can note that, if γ from tree-level decays turns out to be larger than the values in table II, consistency of $\sin 2\beta$ with eq. (1) can be recovered by increasing the side R_t with respect to the SM value (thus shifting the blue area in the figure upwards). As one can see from the same figure, this would also accommodate ϵ_K , since an upward shift in R_t from NP corresponds to $C_s > C_d$ (cf. eqs. (14)-(15)), and could come in particular from $C_d < 1$, as ΔM_d , in contrast to ΔM_s , is directly sensitive to R_t .

Plots analogous to that of fig. 1 (left panel), but with all present uncertainties on the input taken into account, are shown in figures 2 and 3. These plots are obtained by the following procedure. The $\Delta M_d/\Delta M_s$ constraint is used to solve for $\bar{\rho}, \bar{\eta}$ depending on the $\sin 2\beta$ value. The range of solutions implied by the $\Delta M_d/\Delta M_s$ error (with $\bar{\rho}, \bar{\eta}$ highly

correlated) can be translated into a range of values for $|\epsilon_K^{\text{SM}}|$. The rest of the contributions to the ϵ_K error, mostly due to m_c, m_t , to the CKM entry $|V_{cb}|$ and to the assumed ranges for $\hat{B}_K$ and κ_ϵ , can be treated as uncorrelated, and plugged in an error-propagation formula. As one can see, this procedure only assumes that $\Delta M_d/\Delta M_s$ be SM-like.

Figure 2 confirms that the combined information of $\sin 2\beta_{\psi K_s}$ and $|\epsilon_K^{\text{exp}}|$ tends to prefer ‘high’ values of $\hat{B}_K \gtrsim 0.85$ (cf. estimate in [22]). However, use of present errors on $\hat{B}_K$ and ξ_s (both $\approx 5\%$), as in the left panel of fig. 2, impairs any clear-cut conclusion. The situation in the case of $\hat{B}_K$ and ξ_s errors hypothetically halved can be appreciated from the right panel of the same figure, where actually a large part of the improvement is driven by the shrinking in the ξ_s error, allowing a better determination of $\bar{\rho}, \bar{\eta}$. Therefore an alternative or complementary strategy to an improvement in ξ_s would be a major advance in the angle γ through tree-level decays.

Finally, as an alternative viewpoint on the above facts (in particular on the role of the $\hat{B}_K$ and ξ_s errors), figure 3 displays, as a function of $\sin 2\beta$, the $\hat{B}_K$ range compatible with the experimental ϵ_K result. For $\sin 2\beta = \sin 2\beta_{\psi K_s}$ the required $\hat{B}_K$ agrees well with the one found in [22].

4. $S_{\psi\phi}$ and $\sin 2\beta$

As a last case, we would like to focus on the possibility that NP contributions to ϵ_K be negligible, as assumed in [5] and in scenario 3 discussed in the previous section. As one can infer from the above considerations, this would favor values of $\sin 2\beta \gtrsim 0.80$, implying the presence of a sizable new phase in B_d mixing with a possible correlation with the B_s system, which we discuss next.

FIG. 2: $|\epsilon_K^{\text{SM}}|$ vs. $\sin 2\beta$ with inclusion of all input uncertainties. Left panel assumes present $\hat{B}_K$ and ξ_s errors, whereas right panel shows the situation with errors on both quantities shrunk to 2.5%.

Let us start with the B_s mixing phase β_s^{full} , eq. (5), using the information from [2]. In the notation of our eqs. (4)-(5), the range for the NP phase ϕ_s at 95% probability is found to be

$$\phi_s \in [-30.45, -9.29]^\circ \cup [-78.45, -58.2]^\circ, \quad \text{corresponding to } S_{\psi\phi} \in [0.35, 0.89]. \quad (16)$$

Assuming generic NP, the SM contribution to the phase amounts instead to [2] $\beta_s = -1.17(11)^\circ$, where to estimate the error we have simply propagated that on $\sin 2\beta_s$.

Let us now compare these findings with the B_d case. If a NP phase contributes to the mixing amplitude, the CP asymmetry in $B_d \rightarrow \psi K_s$ measures the quantity β_d^{full} (see eq. (5)). Then, one can extract information on the NP phase ϕ_d , provided the SM phase β is estimated in some other way. An example is the determination of ref. [5], where the main assumptions are the absence of NP in the ratio $\Delta M_d/\Delta M_s$ and in ϵ_K (as we are supposing in the present scenario). Using the CKM-

fitter package [35], we find

$$\sin(2\beta) = 0.88^{+0.11}_{-0.12}, \quad (17)$$

where we have used the $\hat{B}_K$ result from ref. [9] and the κ_ϵ factor in table I and, similarly to ref. [5], we have treated all the input errors as Gaussian. The result in eq. (17) is compatible with that of [5]: in particular, the inclusion of the κ_ϵ correction pushes the $\sin 2\beta$ determination further upwards, even if its associated error introduces an additional uncertainty in the ϵ_K evaluation.

If the high value implied by eq. (17) for β were indeed correct, this would indicate the presence of a *negative* NP phase in the B_d system, with absolute value of $\mathcal{O}(10^\circ)$. Quite interestingly, the solutions found in [2] for the NP phase in the B_s system (see eq. (16)) go in the same (negative) direction and the lowest solution is also compatible with $\approx -10^\circ$.

One is then tempted to envisage a scenario characterized by a significant NP phase roughly equal in both B_d and B_s systems, i.e.

$$\phi_B = \phi_d \approx \phi_s \approx -9^\circ \Rightarrow \begin{cases} \beta_{\psi K_s} < \beta \approx 30^\circ \\ S_{\psi\phi} \approx 0.4 \end{cases} \quad (18)$$

with no NP in the K system. The interesting aspect of this scenario is the correlation between new CP violation in the B_d and B_s systems. In the limiting case of exact equality between the NP phases in the two sectors, we show in figure 4 the predicted $S_{\psi\phi}$ as a function of $S_{\psi K_s}$ (see eqs. (1)-(2) for the definitions). If improvements on the $\sin 2\beta$ determination should indicate a large figure like eq. (17) and $S_{\psi\phi}$ were measured as large as 0.4, this could be a hint in favor of this scenario. On the other hand, the scenario in eq. (18) seems to be problematic with regards to the implied $|V_{ub}|$ value. As seen already in the right panel of fig. 1, the value of $|V_{ub}|$ is generically larger than the present exclusive result. To address this issue, we plot in figure 5 the $|V_{ub}|$ range implied by a given

FIG. 3: $\hat{B}_K$ ranges compatible with the experimental ϵ_K result as a function of $\sin 2\beta$. $\hat{B}_K$ and/or ξ_s are taken with present or 2.5% uncertainties (see legend). Comparing red with blue areas one can note the role of a decrease in the ξ_s error.

FIG. 4: CP asymmetry $S_{\psi\phi}$ as a function of $S_{\psi K_s}$ for a common NP phase $\phi_B \in [-12, +2]^\circ$.

FIG. 5: $|V_{ub}|$ ranges implied by a given NP phase in the B_d system, ϕ_d . The green band displays the most recent $|V_{ub}|$ average quoted in the PDG [24].

NP phase ϕ_d . We note that, since $|V_{ub}|$ is determined from the side R_b , its error depends mostly on the $|V_{cb}|$ uncertainty, and is estimated through the propagation formula. On the other hand, for fixed $\sin 2\beta$, $|V_{ub}|$ depends only very weakly on the error due to the $\bar{\rho}, \bar{\eta}$ determination, as expected.

From figure 5 and table II it is evident that $\phi_d \approx -9^\circ$ would imply $|V_{ub}| \approx 4.9 \times 10^{-3}$, which is even higher than the inclusive averages in [36]. For comparison, the most recent combination of the inclusive and exclusive $|V_{ub}|$ determinations quoted in the PDG [24], namely

$$|V_{ub}| = (3.93 \pm 0.36) \times 10^{-3}, \quad (19)$$

is reported in figure 5 as a green band, and can be seen to be compatible with no phase. Results similar to eq. (19) can be found in [37].

Therefore, assuming that $|V_{ub}| \lesssim 4 \times 10^{-3}$ and that $S_{\psi\phi}$ should be confirmed as large as implied by eq. (16), the middle scenario presented in the previous section, characterized by smaller NP effects in both the B_d and K sectors, would be a more plausible possibility. In this case, the NP phases in the B_d and B_s systems would be

(mostly) uncorrelated with each other. In fact, in the case of exact correlation (see figure 4), $\beta \approx 26^\circ$, corresponding to scenario 2, would imply $S_{\psi\phi} \lesssim 0.2$. As for the K system, ascertaining the presence of NP would require a leap forward in the input errors, $\hat{B}_K$ and $|V_{cb}|$ in the first place.

5. Conclusions

In the present paper we have pointed out a possible inconsistency between the size of CP violation in $K - \bar{K}$ and $B_d - \bar{B}_d$ mixing within the SM. The recent decrease in $\hat{B}_K$ from lattice [9, 10] and the inclusion of the suppression factor κ_ϵ in the formula for ϵ_K are mostly responsible for this finding. Such an inconsistency has been already noted in [5], but we differ from that paper as we do not assume the absence of NP in ϵ_K . Moreover, in [5] $\kappa_\epsilon \simeq 0.92$ has not been taken into account.

Under the single assumption that $\Delta M_d/\Delta M_s$ be unaffected by NP, the general pattern of correlations between CP violation in the $K - \bar{K}$ and $B_d - \bar{B}_d$ systems is as follows:

- In the absence of new CP violation in the B_d system, the measured size of $S_{\psi K_s}$ implies ϵ_K with a central value as much as 20% below the data, hinting at NP in $K - \bar{K}$ mixing.
- In the absence of new CP violation in $K - \bar{K}$ mixing, the size of the measured value of ϵ_K implies $\sin 2\beta$ by 10-20% larger [5] than $S_{\psi K_s}$, so that a negative new phase ϕ_d is required in order to fit the experimental value of $S_{\psi K_s}$.
- Since ϕ_d can reach $O(-10^\circ)$, the limiting case of a new phase roughly equal in both B_d and B_s systems allows an enhancement of the asymmetry $S_{\psi\phi}$ by roughly an order of magnitude with respect to its SM value. This could then explain, at least to a first approximation, the effect found in [2].

If, on the other hand, one allows for contributions of NP to $\Delta M_d/\Delta M_s$, so that R_t is increased with respect to its SM value, one can remove the discrepancy between the two systems, provided R_t is increased by, say, 10-15%. This would require, for instance, a destructive interference between SM and NP contributions to ΔM_d – i.e., recalling eq. (14), $C_d < 1$ – and would automatically increase also γ .

Finally, we would like to emphasize that our results are very sensitive to the used value of V_{cb} , as can be anticipated from eq. (15). Therefore, in addition to an accurate calculation of $\hat{B}_K$ and ξ_s , a very precise determination of V_{cb} is required in order to fully exploit the power of the ϵ_K constraint on NP.

We hope that the results and the plots in our paper will help to monitor the developments in the field of $\Delta F = 2$ transitions in the coming years, when various input parameters and the data on CP violation in $b \rightarrow s$ transitions will steadily improve.

Acknowledgments

We thank Uli Nierste for discussions related to section 2, Monika Blanke for critical comments on the manuscript and Federico Mescia for kind feedback on input parameters from Flavianet. We also thank Alexander Lenz and Paride Paradisi for useful discussions. This work has been supported in part by the Cluster of Excellence “Origin and Structure of the Universe” and by the German Bundesministerium für Bildung und Forschung under contract 05HT6WOA. D.G. also warmly acknowledges the support of the A. von Humboldt Stiftung.

Appendix: Estimate of the parameter $\bar{\kappa}_\epsilon$

A rough estimate of the factor $\bar{\kappa}_\epsilon$, discussed at the beginning of section 2, can be obtained as follows. Starting from the general formula for ϵ_K in eq. (9), one finds

$$\bar{\kappa}_\epsilon \simeq 1 + \frac{\xi}{\sqrt{2}|\epsilon_K|} \equiv 1 + \Delta_\epsilon, \quad (\text{A.1})$$

where terms of $\mathcal{O}(\xi^2)$ on the r.h.s. have been neglected. Then Δ_ϵ can in principle be extracted from the analyses of ϵ'/ϵ . One has [18]

$$\frac{\epsilon'}{\epsilon} = -\omega \Delta_\epsilon (1 - \Omega), \quad (\text{A.2})$$

where $\omega = \text{Re}A_2/\text{Re}A_0 = 0.045$ and Ω summarizes the isospin-breaking corrections, that are dominated by electroweak penguin contributions. It is well known that $\Omega > 0$ in the SM and in most known SM extensions. Therefore, setting $\Omega = 0$ and using the experimental value for $\epsilon'/\epsilon = 1.66(26) \times 10^{-3}$ [17], one finds

$$\Delta_\epsilon = -\frac{1}{\omega} \frac{\epsilon'}{\epsilon} = (-3.7 \pm 0.6) \times 10^{-2}, \quad (\text{A.3})$$

which is compatible with [21, 22]. This value can be considered as a plausible lower bound on $|\Delta_\epsilon|$.

However, it is well known that Ω cannot be neglected, but the evaluation of this quantity is subject to significant hadronic uncertainties, although, as discussed in ref. [38], these uncertainties appear to be smaller than in ξ itself. We recall that ξ and Ω are dominated by QCD penguin and electroweak penguin operators respectively, and the evaluation of ξ and Ω requires the knowledge of their hadronic matrix elements.

One method [20] is to evaluate Ω and extract Δ_ϵ from ϵ'/ϵ . From the analysis of [38], that combined various non-perturbative approaches, we find $\Omega = 0.4 \pm 0.1$ in the SM. Yet, one has to remember that Ω is sensitive to NP contributions, in contrast with Δ_ϵ , whose NP sensitivity turns out to be much smaller. For this reason we have also calculated Δ_ϵ directly in the large N_c approach [39]. Both routes give

$$\Delta_\epsilon \simeq -6 \times 10^{-2}. \quad (\text{A.4})$$

Calculations (A.3) and (A.4) and the fact that the SM estimate of ϵ'/ϵ in the large N_c approach agrees well with the data [40] drive us to the estimate

$$\bar{\kappa}_\epsilon \approx 0.94 \pm 0.02. \quad (\text{A.5})$$

This agrees well with the 6% effect estimated in [20]. The error quoted in (A.5) is no more than a guesstimate, but we believe it to be realistic. Clearly a better calculation of $\bar{\kappa}_\epsilon$ should be attempted, using e.g. lattice methods. The result obtained in [22] through a direct calculation of ξ corresponds to $\bar{\kappa}_\epsilon \simeq 0.90(3)$ and implies $\epsilon'/\epsilon \approx 4.5 \times 10^{-3}$ from QCD penguins alone, roughly by a factor 3 larger than the data. Such result requires a very large negative electroweak penguin component for the predicted ϵ'/ϵ to agree with experiment and a certain fine tuning between the two contributions. Consequently we believe that eq. (A.5) represents a very plausible estimate of $\bar{\kappa}_\epsilon$.
